

Silicosis is a chronic disease of the lungs caused by the inhalation of air containing silica dust. It is a grave disease because of its insidious onset and development and lack of dramatic episodes. It is characterized anatomically by a generalized fibrosis of the lungs and clinically by shortness of breath, decreased chest expansion and a progressively lessened capacity for work which is out of proportion to the objective physical findings. The worker's physical condition prior to the exposure is of great importance, since a young, healthy individual can stand a higher concentration or longer exposure before the first stage of silicosis is developed. A pre-existing disease in an individual may be influenced unfavorably by exposure to silica dust.
